CHOOSING OPTIMAL VARIANTS OF PHOTOGRAM METRIC SURVEY WHEN SOLVING THE PROBLEMS OF ROCK MECHANICS AND MINE SURVEYING

J.Korabljov, A.Trunin, It. Fomichov

Moscow, USSR

ABSTRACT: In this article the authors set forth the technique of choosing optimal variants of photogrammetric survey by analytical modelling by means of computers. For choosing an optimal variant of photogrammetric survey when solving a concrete problem, the influence of the various factors (base length, angles of convergence, control points mamber) upon the accuracy of space coordinates determination is investigated on these analytical models.

Not long ago the sole objective of photogrammetry in mining was provision of mines with graphic documentation: plans of mine surveying, profiles, photomaps and photographies. Lately though the scope of problems has considerably widened, especially through investigation of deformations at different sorts of objects: pit slopes, buildings, constructions, frameworks of mining machines, geomechanic models, imitating rock pressure manifestations, underground supports etc. This variety of tasks and conditions emphasizes choosing optimal variant of surveying. Here the preliminary evaluation of some factors' (namely: distance, base length, angle of convergence and inclination, siting and number of control points, brand of camera - photogrammetric or amateur, accuracy of photographs measuring) influence upon the accuracy of results is necessary. Immediate analysis of this influence is hardly feasible and practically im-
possible in many cases.
In VNIMI this problem is solved by a method of computer analytical modelling.

Parametric adjustment of measurements by the least square method in calculation of resection in space is taken as a basis of modelling. The resection in space is calculated with the aid of a well known collinearity equation of image rays:

$$
\left\|\begin{array}{l}
X \\
Z \\
Z
\end{array}\right\|=K \text { 时 }\left\|\begin{array}{l}
X \\
Y \\
Y
\end{array}\right\|
$$

The corrections to preliminary values of data of outer and/or inner orientation are derived from the solution of the set of equations in the form $A X+L=v$ if the condition $\mathrm{pvv}=\min$ is met. Along with that it is possible to determine corrections to the ground coordinates (it is done if only their approximate values are available). Spatial coordinates $X, Y, Z$ and their mean square errors are calculated from the adjusted values of the orientation data when any mutual arrangement of camera and object is possible.

Frecalculation of possible accuracy of surveying requires an analytical model consisting of the totality of points the coordinates of which on the photographic images and in the system of axes of the objects are calculated according to the central projection laws. Ihis model is built and processed by a computer.

In processing of the model two independent components $m_{I X(Y, Z)}$ and $m_{2 X(Y, Z)}$ of the mean square error ${ }_{X}{ }_{X}(Y, Z)$ of coordinates $X, Y, Z$ are calculated. Component $m_{I X(Y, Z)}$ stems from errors of the orientation data and $m_{2 X(Y, Z)}$ - from photo-coordinate errors.

Value of ${ }_{X(Y, Z)}$ is calculated as a root mean square value of the components $m_{I X(Y, Z)}$ and $m_{2 X(Y, Z)}$. The component $m_{\text {IX }}(Y, Z)$ is derived from the formulae:

$$
\begin{align*}
& m_{1 \times(y, z)}=\mu \sqrt{Q_{\times(y, z)}}  \tag{I}\\
& Q_{\times(y, z)}=F_{X(y, z)} B^{-1} F_{X}^{T}(y, z) . \tag{2}
\end{align*}
$$

where $F_{x(y, z)}$ and $F_{x(y, z)}$ are respectively vector and transpose of the vector the elements of which are partial derivatives of functions $X, Y, Z$ with respect to the orientation data;

B-I - inverse matrix of coefficients of normal equation of corrections;
$\mu$ - standard error of unit weight.
The constituent $m \mathrm{x}(\mathrm{y}, \mathrm{z})$ is calculated from the formula:

$$
\begin{equation*}
m_{2 \times(y, z)}^{2}=\sum_{\kappa=1}^{4} f_{\kappa}^{2} m_{\kappa}^{2} \tag{3}
\end{equation*}
$$

where $m_{k}$ - mean square errors of photographic measurements of coordinates $x, y$ and parallaxes $p, q$;
$f_{k}$ - partial derivative of functions $X, Y, Z$ with re-
spect to coordinates and parallaxes.
Analysis and generalization of the processed data and thus revealed regularities of errors distribution serve as
a basis for the choice of optimal survey variant while solving practical problems.

The investigations results are presented in the form of tables and plots of errors distributions.

The study of some factors' influence upon the accuracy of spatial coordinates determination is analysed below.

THE NUMBER AND SITE OF CONTROL POINTS
The study was accomplished on an analytical model which consists of 50 points evenly distributed ( 5 rows with 5 pointis in each) along the near and far (from the centre of projection) facets of rectangular parallelepiped IOOO x I500 X I500 mm in size.

Normal perspective of the survey is imitated with the following parameters: basis - IOOO mm, overlap - 50\%, distance from basis to the near plane of the parallelipiped 2500 mm , focal length and size of pictures are 200 mra and I3 x I8 cm respectively. Only the elements of exterior orientation are corrected in the processing of the model.

Fig. I displays some of the investigated sketches of control points. Values of $Q_{y}$ (see formula 2), mean square errors of $m$ and its components $m_{I}$ and $m_{2}$ (formulae $I$, 3) are presented in table $I$.

The confined space of this paper does not permit to present in full details the results of the studies, therefore table $I$ exibits only $Q_{y} m_{I y}, m_{2 y}, m_{y}$ for the six sketches of control points.

Figs.2,3 show the distribution of vaives $Q_{\pi}, Q_{K,}, Q_{Z}$ (iec. reased for $Q y$ by a factor of IOO) only on sketches 2 and 3 (fig.I) respectively at near and far facets of the model. In calculation of errors it was assumed: $\mu=0,01, \mathrm{~m}_{\mathrm{x}}=\mathrm{m}_{\mathrm{z}}=0,01 \mathrm{~mm}$.

Results of the studies suggest that number of control points influences mainly the values of errors of spatial coordinates whereas their siting sketch affects primarily character of errors distribution on the object of survey. Choosing this or that sketch of control points siting we may enhance (all other things being equal) the accuracy of coordinates determination in prescribed sites of the object or reach uniformity of accuracy throughout the object.

CONVERGENCE OT SURVEYING AXES
Analytical models of symmetrical convergent surveying are calculated by a computer. The parameters of these I2 models are displayed in table 2. "Object of surveying" is a vertical plane with 25 points (the 5 rows of 5 points each). Figs $4 b$ and $4 c$ show only 9 points, remaining Is are symmetrical about $A A$ and $B B$ axes. In calculation the basis was assumed to be horizontal and parallel to the object plane at the distance of 1000 mm from it. Focal length of the pictures was assumed to be equal 1000 x 1000 mm in size (fig.5), whereas No I2 imitates surveying of the plane which expandes with increase of the basis and angle of convergence and conforras in size to the area of stereoscopic pairs with IOO\% overlap (fig.6).

In models processing only elements of exterior orientation were determined with use of four control points. For convenience of the results interpretation the values of were assumed to be equal $0, O I$ and $m_{x}=m_{z}=0, O I \mathrm{~mm}$.

Table 3 displays errors of coordinates detecmination in I2 models.

Fig. 6
of them imitates normal survey with relation $B: Y=0,6$ and the second - symmetrical convergent survey where $B: Y=2,=50$. The accomplished researches enable us to draw following conclusions:
I. The most favourable relation $B: Y$ is in the range from I,5 to 2,5. In this case accuracy of space coordinates determination is not influenced by variations of angle of convergence from $60^{\circ}$ to $120^{\circ}$. With equidistance stereoscopic pair of symmetrical-convergent survey with IOO \% overlap covers an area twice or thrice as big as that covered by stereoscopic pair of normal survey. Errors of space coordinates determination along the $Y$ axis reduce by the factor of $I, 5-2$, along other two axes the variations are negligible.
2. Oncoming survey (with angle of convergence equal to I80) which assures better accuracy of space coordinates determination at the margin of picture may appear useful in surveying the sections of underground workings. Survey with coincident axes has no advantages over other methods of survey whereas the results of position data determination are much more approximate.

As a conclusion we may say that analytical modelling method permits effectively choose optimal variant of photogrammetric survey which secures necessary accuracy in solving mining and other engineering problems with minimal time and labour expenditures.

Conclusions inferred from analytical modelling are in good agreement with the results of processing of real photographies of special stands.

Processing technique serving as a basis of analytical modelling was used in working out recommendations to detecting deformations in buildings, constructions and also in geomechanical models which are being set up to stady rock pressure manifestations.

The same technique was unexpectedly applied in restoration of Voskresensk Cathedral in New Jerusalem Abbey, Istra, near Woscow which was destroyed during the Morld Tar II.

It was necessary to determine some dimensions of the Cathedral's lost elements. Several amateur archive photographs from which stereoscopic pairs could be compiled were used for the purpose. The points of the Cathedral's remaining part were identified on the photographs and their space coordinates were detected by geodethic methods. Some of the identified points were used as control points, the rest were meant to check up the solution of problem.

Accuracy of the dimensions detected by the comparison of results of different stereoscopic pairs processing and by deviations from geodethic values was of the order of $15-20 \mathrm{~cm}$ which appeared quite satisfactory for the demands of the Cathedral's restoration.
