ABSTRACT

We think that rasterphotogrammetry is really suitable for biostereometrics especially employing one photogram. For this purpose it is important to use, with the metric camera, a metric projector: the metric projector is very different from a normal one not only for its optique precision but also because it must take the exterior orientation requested. On the surface of the body to be taken, we project a reticle, consisting of a double series of straight lines intersecting in points called nodes. If we have a normal taking, that it is to say with optique axes of the metric camera and of the projector parallel one to another and normal to the base, the raster will misshape but the horizontal lines of the reticle will remain still horizontal and equidistant in the photogram. Consequently, in order to reconstitute the nodes (the points of the body in which the nodes of the reticle are projected) it is necessary to measure only one coordinate of them on the photogram. It is possible to measure the coordinates automatically and very simple formulas allow to plot them. In order to have a restitution really on line it would be necessary to use a TV metric camera instead of a metric camera but we do not dispose of that one.

INTRODUCTION

When screening examinations are necessary for a particular diagnosis to point out asymmetries or particular pathologies, it is important to simplify the taking as well as the restitution of the photograms. We think that the methodology suitable for this purpose is raster-photogrammetry employing only one photogram and using a metric camera coupled with a metric projector.

The scheme of the metric projector, which is to be produced according to the project of one of the authors, will be briefly illustrated in the following section.

The taking must be normal with the optique axes of the camera and the projector parallel to one another and normal to the base. By doing thus, the projected raster maintains, in the photogram, some characteristics which make measurements simpler to take either by the use of a monocomparator or by automatic procedures. In effect the lines of the projected raster parallel to the base will remain parallel to each other in the photogram.

THE PROJECTOR

The metric projector in its main details has been already described in previous papers (E.Baj: Riprese fotogrammetriche con l'ausilio di un proiettore metrico Bollettino SIFET N° 3/4 1983; E.Baj et alia: Preprocessing procedures for automatic plotting in photogrammetry - International Archives of Photogrammetry Vol. XXV A2 Comm. 11°). A few information are here reported just to enable the readers to understand the procedure: for further details refer to the papers listed above.

First of all it will have the same precision of the metric camera it works with (from the mechanic point of view as well as from the optic one) and it will work on a tripod.

As it is very important to direct easily the projector towards the object to be taken, it will consist of two main parts: an orientable support and a tiltable projector; these rotations, measurable on horizontal and vertical circles allow the projector to assume the exterior orientation requested.

In a metric projector, like in a metric camera, we have to define the interior orientation, i.e.: a) principal distance; b) principal point; c) and the coordinates of the principal point.

- a) We define principal distance as the distance from the internal perspective center (nodal point) to the plane of the reticle measured along the perpendicular to the plane of the reticle: the perpendicular has to be coincident with the optical axis of the lense.
- b) We define principal point as the foot of the perpendicular from the interior perspective center to the plane of the reticle. The reticle, that is coated on an optical glass, is mounted on a frame: the frame is put in situ always in the same position. On the frame there are reference points which determine the X,Y axes.
- c) We define coordinates of principal point as those determined with reference to the X,Y reticle axes. The reticle as mentioned before is made up of two series of parallel lines intersecting at 90° in points called nodes.

Besides, it would be advisable that :

- 1) the principal distance of the camera and of the projector were the same,
- 2) the size of the reticle to be projected were approximately equal to the plate of the camera.

THE TAKING

Because of the delay in the delivery time of the metric projector, it was impossible to employ it for this paper. It was decided not to give up in our study and we went on employing a metric Jenoptik Jena Zeiss UMK 10/13 18 camera and a normal overhead projector we had already used for preliminary trials.

A 20 by 20 cm² high precision Nestler raster with a 1 by 1 mm² grid printed on a transparent glass of selected flat was employed. The scheme of the taking is illustrated in fig. 1. Two metric cameras were employed which were symmetrically located and equidistant from the overhead projector. The aim was to have in the same time two distinct synchronised raster-photograms which, when put together, formed a pair of stereophotograms; thus enabling us to compare the three different possible restitutions.

Before the taking we tried to realize the following conditions by microgeodetic survey:

- a) the metric camera optic axes and the beam projecting the center of the raster (projector axis) parallel to each other, horizontal and at the same height,
- b) the central line of the raster to be projected (x axis) horizontal and parallel to the x axis of the plate plane of the metric camera.

For this purpose two alignments parallel to each other at a distance of 2300 mm (length of the base) and an alignment normal to these ones were traced with a T2 Wild theodolite. The two intersections of these alignments were the stations of the cameras. Then a third alignment parallel to the others was traced passing through the middle point of the base. On the wall, on which the reticle is projected, three targets were put corresponding to the three alignments in order to check the pointing of the cameras and of the projector from the planimetric point of view i.e. their correspondence to the alignments traced by means of a theodolite. The taking is normal with reference to the metric cameras. By means of a NK2 Wild level, in order to check that the axes of the metric cameras were at the same height, we levelled the horizontal fiducial marks of the two metric cameras and we checked that the axis of the projector was lying in the same plane. The two b/2 bases between the camera and the overhead projector are not normal to their axes; infact the positions of their anterior nodal points are not known and so it is impossible to locate them as required in the normal taking.

The horizontal component B_y of the b/2 base in the direction of the axes of the cameras is of the order of a few cm; even though the microgeodetic survey has a very high accuracy there is a slight difference in height between the camera and the projector. These two elements must be taken into account in an analytical restitution. The only definite data are the principal distance of the metric cameras and the horizontal component B_x of the base normal to the camera axes. Anyway, in order to check the results, 4 targets were put in the taking field; the relative positions of which were determined by microgeodetic operations: they are indicated in the scheme of fig. 1. The object of the taking is a male back surface and the aim was to point out the possible asymmetries (fig. 2). For this purpose the choice of the reference plane is very important and it is generally parallel to the median plane; actually a wrong choice could lead to incorrect conclusion.

An expert could object about the rather long distance existing between the taking equipment and the object to be photographed, besides the distribution of some additional targets (check points) put on tripods. Now, we point out that all the takes were carried out as follows :

- in simultaneous shots
- on roll film (18 cm wide, 9 m long)
- in a manner that potentially would let the operator to shot many takes in a speedy sequence. (For this last aspect we have still to select an emulsion which should be very fast and with an high contrast).

Consequently, our choice about the configuration was due two main remarks :

- 1) UMK format and focal length make possible to check the relations between the distance of 5 m (longer than usual in biostereometrics) and the attainable accuracy in the different restitutions.
- 2) The increase in the object distance entails an enlargement, both in the field depth and (consequently) in the application range of the raster-photogrammetry.

The latter remark involves an use in some fields, different from classical Biostereometrics, ad in big animal movement analysis.

RESTITUTION

Raster-photogram - Because of the lack of the metric projector, we had to employ a reticle suitable for the overhead projector: this reticle with lines of different width was not readable by the automatic reading methodology which we are using.

The measurements were done by an operator using an AC1 Wild analytical system as monocomparator. The nodes were collimated with a defined order using suitable code (fig.3). The software system gave the plate coordinates directly. A second special software working on a personal computer can furnish the scientist with the required model coordinates. A proper interface would allow an on line restitution.

Stereo-photograms - The normal stereo-restitution was carried out using the same AC1 Wild analytical system in stereocomparator mode. In such a way we obtained directly the spatial model coordinates which are displayed in table 1. The relevant graphical results (i.e. contour lines and cross sections) are still under preparation at this date, it is expected that they will be ready for the beginning of the Symposium.
